Abstract

We present a new volatility model, simple to implement, that combines various attractive features such as an exponential moving average of the price and a leverage effect. This model is able to capture the so-called “panic effect”, which occurs whenever systematic risk becomes the dominant factor. Consequently, in contrast to other models, this new model is as reactive as the implied volatility indices. We also test the reactivity of our model using extreme events taken from the 470 most liquid European stocks over the last decade. We show that the reactive volatility model is more robust to extreme events, and it allows for the identification of precursors and replicas of extreme events.

Key Words: Volatility, tail event, risk management, asset pricing
JEL Classification: C5, G01, G1, G32

1 Introduction

Stylized facts from the financial markets include heavy tails, extreme correlation and leverage effect (Bouchaud and Potters (2000), Cont (2001)). Various studies suggest that the power law nature of financial returns, \( P\{|r| > x\} \propto x^{-\alpha} \) (at large \( x \)) with a quasi-universal exponent \( \alpha \) close to 3, explains most extreme events, including crashes (Gabaix, Gopikrishnan, Plerou, Stanley (2005)). Stock market crashes can be seen as critical points surrounded by precursors and replicas (Sornette,
Johansen and Bouchaud (1996)). All these extreme events in the time series affect the estimation of the tail dependence measure (Davis and Mikosch (2009)). In particular, when the market is facing extreme negative returns, the level of correlation is significantly higher than during extreme positive returns (Longin and Solnik (2001), Ang and Bekaert (2002)). This pattern can be explained by the asymmetry of volatility that is partly due to the so-called “leverage effect”. The leverage effect is characterized by a surge in volatility and a subsequent drop in the stock price (Black (1976), Christie (1982), Campbell, and Hentchel (1992), Bekaert and Wu (2000)). Bouchaud, Matacz and Potters (2001) study the leverage effect for stocks and stock indices. They find a moderate (strong) correlation with a decay period of 50 (10) days for individual stocks (indices). The correlations for indices are therefore stronger than for stocks, despite the fact that a stock index is merely a portfolio of stocks. They argue that the leverage effect for stocks stems from a simple retarded effect, where price variations are calibrated not on the instantaneous value of the price but on an exponential moving average of the price. Their retarded volatility model adequately represents the leverage effect for individual stocks, which are mainly characterized by idiosyncratic (or specific) risks. However, they recognize that it is no longer the case for stock indices, which are only characterized by systematic risk, whose leverage is driven by another phenomenon, the so-called “panic effect”. This panic effect is partly explained by an increase of correlation between single stocks (Reigneron, Allez and Bouchaud (2011)). Relying on the retarded volatility model of Bouchaud, Matacz and Potters (2001), we develop a new volatility model that (i) conserves the retarded effect property and (ii) adequately extends the leverage effect from the specific single stock case to the systematic case of stock indices, taking into account the panic effect. This model is well suited not only for stock indices but also for single stocks, particularly in times of distress during which stocks are mainly affected by the systematic risk. As emphasized by Allez and Bouchaud (2011), “during large swings of the index, the market exposure of stocks becomes the dominant factor”. First, the reactivity of the model is tested against the European volatility index V2X and is also compared with other models. The comparison to the volatility index is chosen because volatility is not directly observable and market participants prefer using implied volatility indices as market volatility proxies. Thus, how well the model captures the dynamics of such a proxy may be an adequate gauge of quality. Second, the robustness of the model is tested using extreme events. An empirical study is performed on the 470 most liquid European stocks over the last decade. This study investigates extreme systematic and specific risks, which could be responsible for massive losses and are therefore important for investors. Our results suggest that the market shocks are better assimilated into the reactive volatility model.

The article is organized as follows. Section 2 describes the reactive volatility model. Section 3 analyzes the empirical robustness of the model around extreme events. Section 4 summarizes the main findings and provides some concluding remarks.

2 The reactive volatility model

2.1 Model for stock index

Let $I(t)$ be a stock index at equally spaced, discrete times $t$. It is well known that arithmetic returns, $\Delta I(t)/I(t)$, are heteroscedastic partly due to price-volatility correlations. The goal is to define a
convenient estimator, a level $L(t)$, of the stock index $I(t)$ such that the renormalized arithmetic returns, $\Delta I(t)/L(t)$, become more homoscedastic.

Let us introduce two stock index levels as exponential moving averages (EMAs) with two characteristic time scales: a slow level $L_s(t)$ and a fast level $L_f(t)$. These EMAs can be computed using standard linear relations:

\begin{align*}
L_s(t+1) &= (1 - \lambda_s)L_s(t) + \lambda_s I(t+1) \\
L_f(t+1) &= (1 - \lambda_f)L_f(t) + \lambda_f I(t+1)
\end{align*}

where $\lambda_s$ and $\lambda_f$ are the weighting parameters of the EMAs. The appropriate values of $\lambda_s = 0.0241$ and $\lambda_f = 0.1484$ are extracted from the retarded volatility model of Bouchaud, Matacz and Potters (2001). For practical purposes, a filter is introduced to make the estimator more robust against outliers or extreme instantaneous variations of the stock index. We set:

\[
\hat{L}_s(t+1) = I(t+1) F_{\phi} \left( \frac{L_s(t+1)}{I(t+1)} \right)
\]

where a filter function $F_{\phi}(z)$ is proportional to $z$ for small $z$ and saturated to a constant for large $|z|$. We choose $F_{\phi}(z) = \frac{1}{\phi} \frac{z^{2\phi} - 1}{z^{2\phi} + 1}$, where $\phi$ is a parameter that determines the region of linearity of the filter, i.e., a smaller $\phi$ corresponds to wider linearity regions. At $\phi = 0$, there is no filter, $F_0(z) = z$ and $\hat{L}_s(t+1) = L_s(t+1)$. This filter is useful in practice because the leverage effect is linear up to a certain point. Finally, the main equation for the stock index level $L(t)$, in which the fast level is modulated by the filtered slow level, is defined as:

\[
L(t+1) = \hat{L}_s(t+1) F_{\phi} \left( \frac{L_f(t+1)}{I(t+1)} \right) \ell
\]

where $\ell$ is the leverage parameter that describes the amplitude of the leverage effect between stock returns and volatility. The leverage parameter $\ell$ is set to 8 to reproduce the double exponential fit from the retarded volatility model (see Fig. 1 caption for details). Qualitatively, the value of $\ell = 8$ means that if the index varies by 1%, the volatility is expected to vary by $-\ell \times 1% = -8%$. If there is no filter ($\phi = 0$) and $L_f(t+1)$ is close to $I(t+1)$, a Taylor expansion of Eq. (4) yields a simpler form:

\[
L(t+1) \simeq \hat{L}_s(t+1) \left( 1 + \ell \frac{L_f(t+1) - I(t+1)}{L_f(t+1)} \right)
\]

The introduction of the leverage effect into Eq. (4) allows one to use the “corrected” level $L(t)$ instead of $I(t)$, which leads to more homoscedastic stock index returns $\Delta I(t)/L(t)$ than $\Delta I(t)/I(t)$, as tested below.

\footnote{We set $\phi = 1/0.3 \approx 3.3$, which corresponds to a maximum stock index daily variation of $\pm 30\%$, or a maximum drawdown in the order of 30% over $1/\lambda_s \approx 40$ days. For example, during the worst American stock market crash on 19 October 1987, the S&P 500 declined by 22% while the VIX climbed up to 150%.}
An estimator of the renormalized variance $\tilde{\sigma}_{T}^{2}$ is obtained through an EMA based on $L(t)$:

$$\tilde{\sigma}_{T}^{2}(t+1) = (1-\lambda_{\sigma})\sigma_{T}^{2}(t) + \lambda_{\sigma}\left(\frac{\Delta I(t+1)}{L(t+1)}\right)^{2},$$  \hspace{1cm} (6)$$

where $\lambda_{\sigma}$ is a weighting parameter (we set $\lambda_{\sigma} = 0.0241$). Figure 2 shows that $\tilde{\sigma}_{T}^{2}$ yields a stable output in the short term, on which a historical average can be found without deteriorating the reactivity of the estimator. Finally, the reactive volatility model $\sigma_{I}(t)$ for a stock index is defined as:

$$\sigma_{I}(t+1) = \tilde{\sigma}_{I}(t+1)\frac{L(t+1)}{I(t+1)}$$  \hspace{1cm} (7)

2.2 The volatility term structure and the empirical test against the V2X index

We test the reactivity of Eq. (7) against the V2X implied volatility. Because the V2X index is the average of the implied volatilities of the Eurostoxx 50 index with a maturity $T$ of one month, one also needs to consider the volatility term structure of Eq. (7) through $\sigma_{T}^{2}(t)$, defined as:

$$\sigma_{T}^{2}(t) = \frac{1}{T}\int_{t}^{t+T} \sigma_{I}^{2}(t')dt'$$  \hspace{1cm} (8)$$

For this purpose, we introduce a two-factor model with the following two “long-term” volatilities, $\sigma_{Is}(t)$ (the slow factor) and $\sigma_{If}(t)$ (the fast factor). In this model, the instantaneous volatility $\sigma_{I}(t)$ mean-reverts toward the fast “long-term” volatility $\sigma_{If}(t)$, which in turn mean-reverts toward the slow “long-term” volatility $\sigma_{Is}(t)$. The fast and slow “long-term” volatilities are defined as:

$$\sigma_{Is}(t) = \sigma_{I}(t)\frac{I(t)}{L_{s}(t)} \quad \sigma_{If}(t) = \sigma_{I}(t)\frac{I(t)}{L_{f}(t)}$$  \hspace{1cm} (9)$$

to split the squared volatility $\sigma_{I}^{2}(t)$ into three “components”:

$$\sigma_{I}^{2}(t) = (\sigma_{If}^{2}(t) - \sigma_{If}^{2}(t)) + (\sigma_{Is}^{2}(t) - \sigma_{Is}^{2}(t)) + \sigma_{Is}^{2}(t)$$  \hspace{1cm} (10)$$

The empirical observation from Fig. 3 confirms that it is reasonable to assume in the two-factor model that $(\sigma_{If}^{2}(t) - \sigma_{If}^{2}(t))$ and $(\sigma_{Is}^{2}(t) - \sigma_{Is}^{2}(t))$ follow two mean reverting processes with two relaxation rates $\lambda_{s}$ and $\lambda_{f}$, while $\sigma_{Is}^{2}(t)$ varies much slower than the other processes. Without pretending to any rigor, the reactive volatility estimator with the term structure, $\sigma_{T}$, is then estimated as:

$$\sigma_{T}^{2}(t) \approx (\sigma_{I}^{2}(t) - \sigma_{If}^{2}(t))\frac{(1-e^{-\lambda_{f}T})}{\lambda_{f}T} + (\sigma_{I}^{2}(t) - \sigma_{Is}^{2}(t))\frac{(1-e^{-\lambda_{s}T})}{\lambda_{s}T} + \sigma_{Is}^{2}(t)$$  \hspace{1cm} (11)$$

This relation can be seen alternatively as an empirical definition of $\sigma_{T}(t)$ or as a practical recipe for its computation.

Figure 4 compares the implied volatility V2X for Eurostoxx 50 to four different volatility estimators: (i) a standard estimator with an exponential moving average of squared returns:

$$\sigma_{I,SD}^{2}(t+1) = (1-\lambda_{\sigma})\sigma_{I,SD}^{2}(t) + \lambda_{\sigma}\left(\frac{\Delta I(t+1)}{I(t)}\right)^{2}$$  \hspace{1cm} (12)$$
with the same value of the weighted parameter \( \lambda \sigma \); (ii) a GARCH estimator, \( \sigma_{GARCH}(t) \), which is often considered to be the gold standard; (iii) the reactive volatility estimator \( \sigma_{I}(t) \) from Eq. (7) without a term structure; and (iv) the reactive volatility estimator \( \sigma_{T}(t) \) from Eq. (10) with the term structure. One can see that both the standard and GARCH estimators have much lower correlations with V2X than both reactive estimators. Additionally, the term structure model for the reactive volatility estimator, as expected, improves the slope of the linear regression. Indeed, the slope becomes much closer to 1. The \( R^2 \) from the linear regression is relatively high (around 0.45). We can therefore consider the model to be nearly as reactive as the volatility index. One can therefore expect that the model will manage to measure, in a reactive way, not only the risk of the stock index but also the systematic risk of any stock.

2.3 Model for a single stock

For a single stock, the reactive model relies on an equation similar to Eq. (7) used for the stock index:

\[
\sigma_{i}(t + 1) = \tilde{\sigma}_{i}(t + 1) \frac{L_{i}(t + 1)}{P_{i}(t + 1)}
\]

with \( L_{i}(t + 1) \) and \( \tilde{\sigma}_{i}(t + 1) \) obtained through equations similar to Eqs. (4, 6), respectively. The only difference comes from \( \hat{\sigma}_{s}(t + 1) \) in Eq. (4), which applies now to the single stock price \( P_{i}(t) \) instead of the index price \( I(t) \). This formula adequately extends the leverage effect from the specific risk case (already accounted in the retarded volatility model), to the systematic case, which captures the panic effect. In what follows, the reactive volatility estimator \( \sigma_{i}(t) \) from Eq. (13) is tested and used to identify precursors and replicas around extreme events.

3 Empirical test of the reactive volatility model around extreme events

3.1 Data analysis

The database consists of daily price series for the 470 most liquid European stocks from January 1st, 2000 to April 4th, 2012. Let \( P_{i}(t) \) denote the closing price of \( i \)-th stock at day \( t \). From each price series, an array of arithmetic returns, \( R_{i}(t) = \frac{P_{i}(t)-P_{i}(t-1)}{P_{i}(t-1)} \), is constructed. An extreme event is said to occur when the absolute arithmetic return \( |R_{i}(t)| \) is three times larger than the reactive volatility estimator \( \sigma_{i}(t-1) \):

\[
|R_{i}(t)| > 3\sigma_{i}(t-1)
\]

For each stock, we search for extreme events in the array \( \{R_{i}(t)\} \). At each occurrence of an extreme event, we record the subsequence \( \{r(-\Delta), r(-\Delta + 1), ..., r(0), r(1), ..., r(\Delta)\} \) of normalized returns before and after the extreme event (at day \( t \)), \( r(k) = R_{i}(t+k)/\sigma_{i}(t+k-1) \) \((k = -\Delta, ..., \Delta)\), where \( \Delta \) is a fixed subsequence length with \( \Delta = 9 \) trading days. The subsequence \( \{r(k)\} \) characterizes

\[^{2}\text{The length is fixed to 9 trading days after having considered up to \( \pm 100 \) days; empirically, after 9 days, the marginal gain in precision can be neglected.}\]
the behavior of a stock before and after an extreme event, which is identified by the magnitude of \( r(0) \) (we drop the index \( i \) because the extreme events will be analyzed for all stocks together). Repeating this procedure for each stock generates a database of 10,213 extreme events. Note that if two (or more) extreme events occurred within \( \Delta \) days, only the first one is retained, while any later events are ignored. It is worth emphasizing that the above definition of an extreme event is purely conventional, as is the choice for the threshold \( 3\sigma_i(t-1) \). Note also that if stock returns were Gaussian, the number of extreme events would be much smaller than what we observe because the probability of a return larger than \( 3\sigma \) is 0.0027.

A closer look into the statistical properties of stock returns around extreme events requires distinguishing the systematic risk from the specific risk. The systematic risk mainly affects the stock indices (or even every stock during stress conditions), while the specific risk mainly affects single stocks. More precisely, the database records are split into four groups that are denoted “systematic positive” (SyP), “systematic negative” (SyN), “specific positive” (SpP) and “specific negative” (SpN). The division into positive and negative groups is determined by the sign of the extreme normalized return \( r(0) \). The division into systematic and specific groups is decided by the condition of the Eurostoxx index \( I(t) \) on the day \( t \) of an extreme return: if \( |\Delta I(t)| \) exceeds 3\%, the extreme event is categorized as systematic, otherwise as specific. Both systematic groups (SyP & SyN) contain the records of extreme returns from individual stocks that are affected by large stock index returns, representing extreme events for the entire market. The specific groups (SpP & SpN) contain the records of extreme returns that are specific to individual stocks. The database of extreme events contains 903 systematic positive records, 1,046 systematic negative records, 5,135 specific positive records and 3,129 specific negative records.

To qualitatively separate the possible sources of deviations (accuracy of the reactive volatility estimator and return correlations), a second database of “non-extreme” events is constructed with the same structure, in which dates \( t \) are chosen randomly (without the selective condition (14)). In this case, no strong correlations between successive returns are expected, and the reactive volatility estimator is expected to accurately capture the stock’s fluctuations.

### 3.2 Empirical results

The behavior of the reactive volatility model around extreme events is characterized by the following function:

\[
q_k = \sqrt{\langle r^2(k) \rangle} - 1 \quad (k = -\Delta \ldots \Delta)
\]

where the arithmetic average \( \langle \ldots \rangle \) is taken over all records in the chosen group (SyP, SyN, SpP, SpN). For the idealized case in which the returns are uncorrelated and the reactive volatility estimator \( \sigma_i(t) \) is exact, the average \( \langle r^2(k) \rangle \) of normalized returns should be equal to 1, so that \( q_k \) would be 0, except for \( k = 0 \). In other words, the deviations of \( q_k \) from 0 characterize the accuracy of the volatility estimator.

Table 1 summarizes the average characteristics obtained for both estimators. The level of deviations \( q_k \) is averaged over 9 days before and after an extreme event, as illustrated in Figs. 3-8. For all groups of extreme events, this level is significantly higher for the standard volatility estimator than for the reactive volatility model because the latter captures the panic effect for the systematic
groups and the retarded effect for the specific groups. One can conclude that the reactive volatility model is more robust in the face of extreme events, and its recovery after a shock is faster.

Figure 5 shows $q_k$ for the four groups. Full circles represent $q_k$ from the database of extreme events, while the solid line is used as a reference level from the database of random events (extreme or not). The solid line is close to 0, which indicates that the reactive volatility model is accurate for ordinary days (without extreme events). For comparison, Fig. 6 shows the same quantities computed by replacing $\sigma_i(t)$ in (14) with an empirical measure of volatility, $\sigma_{i,SD}(t)$, which is obtained from a standard volatility estimator with an exponential moving average:

$$\sigma_{i,SD}(t + 1) = (1 - \lambda_{\sigma})\sigma_{i,SD}(t) + \lambda_{\sigma}[R_i(t + 1)]^2$$

with the same value of the weighting parameter $\lambda_{\sigma}$.

Let us now take a closer look at the results of Fig. 5. For systematic groups, there are significant deviations of $q_k$ from 0 before and after an extreme event. In other words, the normalized returns before and after an extreme event are significantly larger than typical normalized returns.

In the systematic positive group, the observation of relatively strong precursors might be partly explained by earlier market instabilities. Indeed, most of the extreme events in that case come from political or monetary decisions made in reaction to earlier market instabilities.

For the systematic negative group, the observation of excitements before an extreme event is less intuitive. These variations could come from the possibility that some investors anticipate the release of very bad economic news earlier than others. After an extreme event, large renormalized returns are naturally expected as the market relaxes after this event. It signifies that investors should be worried about replicas after the initial extreme event and that most models consistently underestimate risk.

Figure 5c and Fig. 5d for both specific groups indicate less significant deviations of $q_k$ from 0 before an extreme event.

In the specific positive group, the observation of an extreme positive return can be caused by announcements of corporate decisions (mergers or acquisitions). Because these corporate decisions remain strictly confidential and are difficult to anticipate, one expects to observe very weak precursors and small values of $q_k$ for negative $k$. After the day of announcement, the stock returns may experience a rapid relaxation (one or two days) towards the normal level of small $q_k$ for positive $k$.

For the specific negative group, the observation of an extreme event can be caused by an announcement of corporate decisions related to bad economic results for the company (profit warning, bankruptcy, or downgrade). This kind of news is partly anticipated by the market through rumors. One therefore can identify stronger precursors of extreme events. Because the situation of the company remains tenuous, stronger replicas are also identified.

We manage to identify statistically the presence of precursors of extreme events in each case, but the precursors remain too weak to be detected one by one to forecast the occurrence of an extreme event.

Similar plots in Fig. 6 for a standard volatility estimator display a less reactive measure around extreme events.

Figure 7 shows the asymptotic behavior of the probability density $p(z)$ of extreme normalized returns for the four groups. In all cases, power law decays $z^{-1-\alpha}$ are observed, with the exponent $\alpha$
equal to 5.5, 4.5, 3.5 and 3.2 for the SyP, SyN, SpP and SpN groups, respectively. For the systematic groups, the exponent is greater than 4, indicating the existence of kurtosis. The renormalization of returns with the reactive volatility model has managed to increase the exponent from 3 to 5, which means that this model is able to capture most of the extreme events. For the specific groups, the exponent remains around 3. Most of these extreme risks come from very specific news (for example, a takeover offer), and most of the time the price jumps, but the volatility does not change.

4 Conclusion

We develop a new volatility model, easy to implement, that combines several attractive features, including an exponential moving average of the price and a leverage effect. In addition, the model is able to capture both the panic effect induced by the systematic risk and the retarded effect induced by the specific risk. The model is shown to be as reactive as the implied volatility indices, which is an improvement over other models. To test the robustness of the reactive volatility model near extreme events, an empirical study is performed on the 470 most liquid European stocks from January 1st, 2000 to April 4th, 2012. The reactive volatility model is used to renormalize daily returns, among which extreme events are identified and split into four groups: systematic positive, systematic negative, specific positive and specific negative. Our results suggest that the market shocks are better assimilated into the reactive volatility model. Moreover, it identifies precursors and replicas. The model captures much of the extreme systematic risk and a significant part of the extreme specific risk. Future research will include an application of the reactive volatility model to estimate market beta, the aggregation of risk and VaR of a Long/Short portfolio.
References

Table 1: The level of deviations $q_k$ is averaged over 9 days before and after an extreme event. For all groups of extreme events, this level is significantly higher for a standard volatility estimator than for the reactive volatility model because the latter captures the panic effect for the systematic groups and the retarded effect for the specific groups. Note also that the recovery after an extreme event takes, on average, 2.95 days for the reactive volatility model, as opposed to 5.29 days for a standard estimator (both times are estimated from an exponential fit of $q_k$ after an extreme event; see Fig. 5). As a consequence, the reactive volatility model is qualified as more robust in response to extreme events.

Figure 1: The return-volatility correlation (leverage effect), $\mathcal{L}(\tau) \equiv \langle [\delta x(t+\tau)]^2 \delta x(t) \rangle / \langle [\delta x(t)]^2 \rangle^2$, with $\delta x(t) = \Delta I(t)/I(t)$, for simulated data (symbols), and the exponential curve $\mathcal{L}(\tau) \approx -A_I \exp(-\tau/T_I)$, with $A_I = 18$ and $T_I = 9.3$ (days), as introduced and calibrated by Bouchaud, Matacz, and Potters (2001). The simulated data are obtained from a Monte Carlo generated price series of 10,000 points, with $I(t+1) = I(t)(1 + \sigma_I(t) \varepsilon_t)$, in which i.i.d. $\varepsilon_t \sim \mathcal{N}(0, 1)$, and $\sigma_I(t)$ is given by Eq. (7) with a constant $\tilde{\sigma}_I(t) = 0.01$. This figure supports the claim that the reactive volatility model captures the leverage effect, using the correct parameters $A_I$ and $T_I$ calibrated from the empirical stock indices.
Figure 2: The measures of index volatility, $\sigma_I(t)$, from the reactive volatility model (dashed blue line) and the renormalized volatility $\tilde{\sigma}_I(t)$ (solid red line), for the period from 22/06/1998 to 18/05/2012. The renormalized volatility is less volatile in the short term but is able to capture all the long-term moves.

Figure 3: Empirical behavior of three “components” in Eq. (10): $(\sigma_I^2(t) - \sigma_{I_f}^2(t))$ (dotted blue line), $(\sigma_{I_f}^2(t) - \sigma_{I_s}^2(t))$ (dashed green line, which is shifted by −2000 along the vertical axis), and $\sigma_{I_s}^2(t)$ (solid red line). The first two components seem to be mean reverting processes with different relaxation rates, while the last varies much more slowly than the others.
Figure 4: Correlations between increments $\delta(V2X)$ of the Eurostoxx 50 implied volatility index V2X (vertical axis) and increments of four different volatility estimators (horizontal axis): (a) a standard estimator with squared returns; (b) a standard GARCH estimator; (c) the reactive volatility estimator without a term structure; and (d) the reactive volatility estimator with a term structure. First, the increments in volatility for both the standard volatility and GARCH estimators are much more strongly skewed towards positive values. Second, the correlations between the V2X and both reactive volatility estimators are much higher. Finally, accounting for the term volatility structure increases the slope of a linear regression from 0.392 to 0.862, with the latter value being close to 1.
Figure 5: Distribution of $q_k$ around an extreme event for the reactive volatility model. Extreme returns are split into four groups: (a) SyP, (b) SyN, (c) SpP, and (d) SpN. A stock return is termed extreme when it exceeds threefold the empirical volatility $\sigma_i(t-1)$ from the reactive volatility model. The selected interval is ±9 days.
Figure 6: Distribution of $q_k$ around an extreme event for a standard volatility estimator. Extreme returns are split into four groups: (a) SyP, (b) SyN, (c) SpP and (d) SpN. A stock return is termed extreme when it exceeds threefold the empirical volatility $\sigma_{i,SD}(t-1)$ from a standard volatility estimator. The selected interval is ±9 days.
Figure 7: Asymptotic behavior of the probability density $p(z)$ of extreme normalized returns for the four groups: (a) SyP, (b) SyN, (c) SpP and (d) SpN. In all cases, power law decays $p(z) \propto z^{-1-\alpha}$ are observed, with the exponents 5.5, 4.5, 3.5 and 3.2 for the systematic positive, systematic negative, specific positive and specific negative groups, respectively. For the systematic groups, the exponent is greater than 4, indicating the existence of kurtosis, while for the specific groups, the exponent is less than 4.
